Supporting Information

ABSTRACT: It was recently shown that block copolymers (BCPs) produced room-temperature ferromagnetic materials (RTFMs) due to their nanoscopic ordering and the cylindrical phase yielded the highest coercivity. Here, a series of metal-containing block-random copolymers composed of an alkyl-functionalized homo block (C₁₆) and a random block of cobalt complex- (Co) and ferrocene-functionalized (Fe) units was synthesized via ring-opening metathesis polymerization. Taking advantage of the block-random architecture, the influence of dipolar interactions on the magnetic properties of these nanostructured BCP materials was studied by varying the molar ratio of the Co units to the Fe units, while maintaining the cylindrical phase-separated morphology. DC magnetic measurements, including magnetization versus field, zero-field-cooled, and field-cooled, as well as AC susceptibility measurements showed that the magnetic properties of the nanostructured BCP materials could be easily tuned by diluting the cobalt density with Fe units in the cylindrical domains. Decreasing the cobalt density weakened the dipolar interactions of the cobalt nanoparticles, leading to the transition from a room temperature ferromagnetic (RTF) to a superparamagnetic material. These results confirmed that dipolar interactions of the cobalt nanoparticles within the phase-separated domains were responsible for the RTF properties of the nanostructured BCP materials.

INTRODUCTION

Nanostructured materials, defined as having at least one dimension between 1 and 100 nm, have attracted intense research interest in recent years as they often exhibit novel and enhanced properties over their bulk counterparts. Magnetic nanostructures are a particularly interesting class of materials for both scientific and technological reasons, with potential applications including high density information storage, spintronics, magnetic microelectromechanical systems, and biosensors. Commercial magnetic nanostructure fabrication is dominated by conventional "top-down" techniques such as photolithography, electron-beam lithography, and X-ray lithography, most of which involve multiple steps and expensive instrumentation. Alternatively, the self-assembly of block copolymers (BCPs) provides a cost-effective and rapid "bottom-up" approach that can outperform many "top-down" techniques in terms of feature size, periodic length scale, and simplicity.

Recently, we reported a straightforward method to generate room-temperature ferromagnetic materials (RTFMs) from nanostructured BCPs with cobalt nanoparticles confined in one specific phase. The results showed that the nanostructured morphologies were critical, and the room temperature ferromagnetic (RTF) behavior of the BCPs was thought to arise from enhanced dipolar interactions under nanoco confinement between the otherwise superparamagnetic cobalt nano-

results and discussion

Monomer Synthesis. The same strained tricyclic monomer structure was used to provide similar polymerization rates and excellent initiation between blocks (Figure S1). The alkyl-functionalized monomer 2 was synthesized according to established procedures. Treatment of ferrocenemethanol with compound 1 afforded the Fe monomer via Mitsunobu coupling (see Supporting Information for experimental details). The alkyl chain length of monomer 2 influences the microphase separation of the resulting BCPs, and a length of 16 \( (\text{C}_{16}) \) was chosen based on previous studies in which it exhibited the most well-defined microdomains. \(^{14} \)

Polymer Synthesis. Block-random copolymers, \( \text{Poly1}−\text{Poly7} \), with a \( \text{C}_{16} \) home block and a Co-\( r \)-Fe block were synthesized by the stepwise polymerization of each block, as shown in Figure 1. First, the \( \text{C}_{16} \) homopolymer was prepared from monomer 2 by ROMP using the third generation Grubbs' catalyst (G3). When monomer 2 was completely consumed after 6 min, a mixture of monomers 4 and 5 was added to generate the block-random copolymers. The whole polymerization process required less than 15 min, and the monomer conversions for all of the polymers were \( \sim 99\% \), highlighting the efficiency of ROMP.

To study the effect of the cobalt density in the cylindrical domains on the magnetic properties of the nanostructured BCP materials, a series of seven different block-random copolymers were synthesized. The composition details are listed in Table 1.

\(*^{\text{a}}\) Determined by GPC in THF using refractive index (RI) detector, relative to polystyrene standards. \(*^{\text{b}}\) Molar ratio of the Co units \( (x) \) to the Fe units \( (y) \) in the random block calculated from \( ^1\text{H} \) NMR integration. The deviation from the feed ratio is likely due to error in the NMR integration, as the characteristic peak used for monomer 5 is close to peaks at 4.62–4.32 ppm, which are attributed to the protons from the oxanorbornene backbone and the methylene group in the Fe units (Figure S2).

All of the copolymers had similar molecular weights (MW) and narrow polydispersity indices (PDI). The molar ratio of the Co units (4) to the Fe units (5) in the Co-\( r \)-Fe block was varied from 80:20 to 20:80. Meanwhile, the volume fraction of the Co-\( r \)-Fe block was kept constant (0.23 ± 0.01) to ensure the same phase-separated morphology.

Polymer Characterization. The diblock architecture of the resulting copolymers was confirmed by gel permeation chromatography (GPC). Figure 2 shows representative GPC curves for the first \( \text{C}_{16} \) block and the final \( \text{C}_{16}-b-(\text{Co}-r \text{-Fe}) \)
The random copolymerization kinetics of the second Co-r-Fe block were investigated by $^1$H NMR spectroscopy. Figure 3A shows the conversion as a function of time for the copolymerization of the Co monomer 4 (blue) and the Fe monomer 5 (red) for Poly4 (feed ratio of 4 to 5 = 50/50). The conversions of the two monomers were almost identical at each time point, and both reached nearly 100% after 7 min. A living copolymerization conducted isothermally is expected to be a first-order reaction, and this should hold true for a random (gradient-free) copolymerization, as the relative monomer composition does not change with time. Figure 3B shows the first-order time–conversion plots of monomer 4 (blue), monomer 5 (red), and the sum of 4 and 5 (black). The $[M]_0/\Delta [M]$ values ([M] denotes the monomer concentration) were obtained from the ordinate of Figure 3A. All three plots are linear, consistent with a polymerization that follows first-order kinetics with respect to the monomer. The monomer reactivity ratios, $r_1$ and $r_2$, for the living random copolymerization of monomers 4 and 5 were determined by the Fineman–Ross method (Figure S3): $r_1$ = 0.89, $r_2$ = 1.67 ($M_1$ = monomer 4, $M_2$ = monomer 5). Although the $r_1$ and $r_2$ values calculated by this method should be treated with caution due to the steady-state assumption, they indicate that the distribution of monomers 4 and 5 in the Co-r-Fe block is close to truly random.

Self-Assembly and Morphology Characterization. Solvent annealing was utilized to induce the self-assembly of the block-random copolymers, from a film formed by drop-casting a 10 wt% chloroform solution into a Teflon mold. Small angle X-ray scattering (SAXS) and transmission electron microscopy (TEM) were used to characterize the morphologies of the resulting samples. After solvent annealing, the SAXS profiles of the block-random copolymers all showed peaks corresponding to $q^*$, $\sqrt{3}q^*$, and $\sqrt{7}q^*$ ($q^*$ denotes the primary scattering peak), indicating cylindrical morphologies. A representative SAXS profile for Poly5 is shown in Figure 4A, and Figure 4B shows a representative bright field TEM image of the unstained solvent-annealed sample, providing clear evidence for the formation of well-defined phase-separated nanodomains. The dark contrast of the cylindrical domains is attributed to the presence of the heavy cobalt and iron atoms. The $d$-spacings were calculated from the SAXS data according to the equation $d = 2\pi/q^*$. The nanostructures obtained from Poly1–Poly7 exhibited similar bulk periodicities, with $d$-spacings ranging from 42 to 54 nm which is consistent with the diameters (∼20 nm) of the metal-containing cylindrical domains obtained from the TEM images (Table 2).

Heat Treatment and Magnetic Properties. Our previous study showed that upon a simple heat treatment, the cobalt complex-containing diblock copolymers were converted to RTFMs while retaining their phase-separated morphology. The thermal removal of carbonyl ligands from dicobalt hexacarbonyl metal complexes is well-known. Thermogravimetric analysis (TGA) showed that the loss of the carbonyl moieties occurred between ∼110–200 °C for the Co
The nature of the ferromagnetic domains in FeCo block copolymers (Figure 5). The C16-Fe block in Figure 5. The C16-

homopolymer (Figure S4), and the weight loss indicated that about 94% of the carbonyl ligands were removed. By comparison, the C16 and Fe homopolymers showed no mass loss until above 350 °C. The samples were characterized by SAXS and TEM before and after heat treatment, and no significant changes to the morphology were observed (Figure S5).

A typical feature of magnetic nanoparticles is the irreversible magnetic behavior below a field-dependent blocking temperature (or irreversible temperature, \( T_{irr} \)). The irreversible temperature indicates the onset of blocking for the largest particles in the magnetic materials. Above \( T_{irr} \), the ZFC and FC magnetization curves coincide, and the magnetic particles are superparamagnetic; below \( T_{irr} \), the ZFC and FC magnetization curves separate, and the magnetic particles are ferromagnetic. Experimentally, \( T_{irr} \) is defined as the temperature at which the difference between the ZFC and FC magnetizations is less than or equal to 1% of the FC results are included in Figure 5. As the cobalt density in the cylindrical domains decreased, the coercivity of the nanostructured BCP materials decreased from greater than 250 Oe to almost zero, consistent with our hypothesis.

**ZFC-FC Magnetization Measurement.** The effect of the cobalt density within the cylindrical domains on the dipolar interactions between cobalt nanoparticles was further investigated by ZFC and FC magnetization measurements. Figure 6 shows the ZFC and FC curves for three different nanostructured BCP materials with (A) 100%, (B) 66%, and (C) 13% Co units in the cylindrical domains. The lower curves, labeled ZFC (black), were obtained by first cooling the samples from room temperature to 2 K in the absence of a magnetic field. A magnetic field of 100 Oe was then applied, and the magnetization was measured with increasing temperature from 0 to 350 K. The FC upper curves (red) were obtained in a similar way except that the samples were cooled in the measuring field (100 Oe).

A typical feature of magnetic nanoparticles is the irreversible magnetic behavior below a field-dependent blocking temperature (or irreversible temperature, \( T_{irr} \)). The irreversible temperature indicates the onset of blocking for the largest particles in the magnetic materials. Above \( T_{irr} \), the ZFC and FC magnetization curves coincide, and the magnetic particles are superparamagnetic; below \( T_{irr} \), the ZFC and FC magnetization curves separate, and the magnetic particles are ferromagnetic. Experimentally, \( T_{irr} \) is defined as the temperature at which the difference between the ZFC and FC magnetizations is less than or equal to 1% of the FC results are included in Figure 5. As the cobalt density in the cylindrical domains decreased, the coercivity of the nanostructured BCP materials decreased from greater than 250 Oe to almost zero, consistent with our hypothesis.

**M–H Measurement.** If the RTF behavior of the previously reported nanostructured BCP materials was due to the enhanced dipolar interactions between the cobalt nanoparticles under nanoconfinement, decreasing the Co unit percentage should dilute the density of the cobalt nanoparticles in the domains and weaken the dipolar interactions between them, leading to lower coercivity values. To investigate the effect of the cobalt density on the magnetic properties of the nanostructured BCP materials, the magnetization as a function of the applied field (M–H) was measured at room temperature by a superconducting quantum interference device (SQUID) for all of the thermally treated block-random copolymers. As shown in Figure S6, the saturation magnetization values decreased with decreasing Co unit percentage in the Co-r-Fe block (i.e., decreasing cobalt density in the cylindrical domains). The coercivity values at room temperature (in Oe) were obtained from the x-intercepts of the hysteresis loops and are plotted as a function of the Co unit percentage in the Co-r-Fe block in Figure 5. The Co-r-Fe block calculated based on density data which were obtained by the gradient density column method. Co unit percentage in the Co-r-Fe block calculated from 1H NMR integration (Figure S2). Bulk periodicity: \( d = \frac{2\pi}{q^*} \), where \( q^* \) is the primary scattering peak as determined by SAXS. Diameter of the cylindrical domains (\( d_{cyl} \)) determined from the TEM images.
A decrease in dipolar interactions is known to shift irreversible temperatures (66%, and (C) 13% Co units in the cylindrical domains. The 100 Oe for the nanostructured BCP materials with (A) 100%, (B) 66%, and (C) 13% Co units in the cylindrical domains decreased, the peak temperature of the ZFC magnetization curve decreased as well, indicating a decrease in the dipolar interactions, following the same trend observed for both coercivity and $T_{irr}$.

**Figure 6.** ZFC and FC magnetization curves under an applied field of 100 Oe for the nanostructured BCP materials with (A) 100%, (B) 66%, and (C) 13% Co units in the cylindrical domains. The irreversible temperatures ($T_{irr}$) for the samples are indicated on the plots.

For all three samples investigated, $\chi'$ decreased with increasing frequency, which is consistent with other interacting magnetic systems, like spin glasses. However, $\chi'$ also increased with temperature and no peaks were observed in the temperature range investigated, which distinguishes the magnetic behavior of this system from that of canonical spin glass systems. The peak in $\chi'$ observed in spin glass systems is often interpreted as a phase transition between different magnetic states. Although the lack of peaks in the $\chi'$ curves prevented the determination of the intrinsic relaxation times and energy barriers by an Arrhenius plot, $\chi'$ for the 100% Co sample (Figure 7A) increased continuously with temper-
nature, whereas saturation in $\chi'$ as a function of temperature was observed for the 66% and 13% Co samples (Figure 7B,C). Additionally, the saturation temperature for the 66% Co sample (∼300 K) was clearly higher than that of the 13% Co sample (∼225 K). It has been reported that with increasing dipolar interactions, the peak in the $\chi'$ curve shifts toward higher temperatures.\textsuperscript{17,25} For our system, although no peak in $\chi'$ was observed, the $\chi'$ saturation temperatures followed the same trend. With decreasing cobalt density in the cylindrical domains, the dipolar interactions decreased. This was measured by a decrease in the $\chi'$ saturation temperature, which is in accordance with the results from the $M-H$ and ZFC-FC studies.

All of the magnetic measurements, including $M-H$, ZFC-FC, and AC susceptibility studies, are consistent with and support the idea that for our nanostructured BCP materials, diluting the density of cobalt units in the primary sequence weakens the RTF properties of the resulting materials due to interparticle dipolar interactions under nanoconfinement. As depicted in Figure 8, with decreasing cobalt density in the cylindrical domains, fewer cobalt nanoparticles are formed, and the collective magnetic spins resulting from dipolar interactions between cobalt nanoparticles become smaller, leading to weaker ferromagnetic properties. The formation of ∼5 nm cobalt nanoparticles in the 100% Co sample (C\textsubscript{16}-b-Co copolymer) was confirmed previously.\textsuperscript{14} Given the whole collection of magnetic data, it seems safe to assume similar sized particles are formed by these new BCPs. Even if the particle size is smaller than 5 nm, they are still below the critical size for cobalt nanoparticles (10–12 nm);\textsuperscript{51} therefore, the only way the samples reported here can be RTFMs is by having dipolar interactions among the particles assisted by the overall cylindrical shape anisotropy.\textsuperscript{51} At the same time, it is unlikely (practically impossible) that nanoparticles are not formed at all as the cobalt density is decreased based on the ZFC-FC and AC measurements. For example, if no particles were present, there would be no dipolar interactions in the system, and the $T_{irr}$ would be absent. However, even for the 13% Co sample which contains the least number of cobalt-containing monomers, $T_{irr}$ is above 100 K, and the saturation temperature in the AC susceptibility measurement is above 200 K, indicating that there are dipolar interactions present in this system.

**CONCLUSIONS**

A straightforward synthetic approach based on ROMP was used to synthesize novel metal-containing block-random copolymers composed of a well-defined alkyl-functionalized (C\textsubscript{16}) homo...
block and a random block with cobalt complex- (Co) and ferrocene-functionalized (Fe) units. Kinetic studies showed that the random copolymerization of the Co monomer and the Fe monomer was a first-order reaction and close to “ideal”. Holding the morphology constant and varying the molar ratio of the Co units to the Fe units in the random block showed that the cobalt density within the cylindrical domains directly impacted the RTF properties of the nanostructured BCP materials. This was consistent with the hypothesis that the RTF behavior of the nanostructured BCP materials was due to enhanced dipolar interactions under nanoconfinement between the otherwise superparamagnetic cobalt nanoparticles. This paper demonstrates the ability to systematically tune the magnetic properties by controlling the density of the magnetic species at the monomer, or primary sequence, level. These BCPs provide a new model system to study magnetic nanoparticles under confinement. The synthetic ease should allow them to be widely studied. Further functionalization with other metal species is expected to increase the range of properties. These RTFM s demonstrate the concept that learning to build chemically rich polymers will lead to new and unexpected materials.
